A rapid method for isolation of stable niaD and crnA mutants of entomopathogenic fungi Beauveria bassiana and Metarhizium anisopliae

Abstract
Generally niaD mutants of fungi are selected by spontaneous mutations on appropriate minimal medium supplemented with various concentrations of KClO3 and a nitrogen source (Daboussi et al. 1989 Curr. Genet. 15:453-456; Johnstone et al. 1990 Gene 90:181-192; Malardier et al. 1989 Gene 78:147-156; Unkles et al. 1989 Gene 78:157-166). But in case of entomopathogenic fungi it has been observed that niaD mutants isolated simply by spontaneous mutation on chlorate were not stable, (Table-1). Therefore a method has been developed to isolate stable niaD mutants of these fungi by treating protoplasts with ethane methane sulfonate (EMS).

A rapid method for isolation of stable \textit{niaD} and \textit{crnA} mutants of entomopathogenic fungi \textit{Beauveria bassiana} and \textit{Metarhizium anisopliae}

S. S. Sandhu\textsuperscript{1} and G. Venkateswerlu\textsuperscript{2} - \textsuperscript{1}Dept. of Biological Science, R.D.University, Jabalpur, \textsuperscript{2}Dept. of Biochemistry, Osmania University, Hyderabad, India

Generally \textit{niaD} mutants of fungi are selected by spontaneous mutations on appropriate minimal medium supplemented with various concentrations of KClO\textsubscript{3} and a nitrogen source (Daboussi \textit{et al}. 1989 Curr. Genet. \textbf{15}:453-456; Johnstone \textit{et al}. 1990 Gene \textbf{90}:181-192; Malardier \textit{et al}.1989 Gene \textbf{78}:147-156; Unkles \textit{et al}.1989 Gene \textbf{78}:157-166). But in case of entomopathogenic fungi it has been observed that \textit{niaD} mutants isolated simply by spontaneous mutation on chlorate were not stable, (Table-1). Therefore a method has been developed to isolate stable \textit{niaD} mutants of these fungi by treating protoplasts with ethane methane sulfonate (EMS).

The method reported here is advantageous as it yielded more mutants when compared to the method of spontaneous mutation. Secondly, mutants obtained by EMS treatment were more stable than spontaneous \textit{niaD} mutants. Their reversion frequency was less than one in $10^7$ viable conidia, whereas comparatively high reversion frequency was obtained, 100 and 60 in 10\textsuperscript{7} viable conidia of spontaneous mutants of \textit{Metarhizium anisopliae} and \textit{Beauveria bassiana}, respectively. Protoplasts of \textit{B. bassiana} and \textit{M. anisopliae} obtained by the method of Shimizu, 1986 J. Seric. Sci. Japan \textbf{5}:510- 517,(approximately $10^6$) were incubated with 15 ul ethane methane sulfonate (d=1.17g, Sigma) in 1 ml of stabilizing medium (0.02M phosphate buffer pH 7.2 containing 0.6M KCl and 2mM MgCl\textsubscript{2}) at 28 +/- 1 C for 1 h. These protoplasts were then washed twice with 10 ml of stabilizing medium by centrifuging at 1,000 X g for 10 minutes, diluted and then spread on plates containing a regeneration medium (2% sucrose; 1% peptone; 0.5% NaCl; 3% yeast extract and 2% agar agar, pH 7.0). Conidia from surviving colonies were harvested and suspended in Tween 80 aqueous suspension (50 ul/100 ml distilled water). Dilutions of this suspension were plated again on a minimal medium (1% glucose; 0.1% K\textsubscript{2}HPO\textsubscript{4}; 0.5% MgSO\textsubscript{4}; 0.5% KCl; 0.001% FeSO\textsubscript{4}; 7H\textsubscript{2}O; 0.005% EDTA disodium salt, pH 6.5) containing 10 mM glutamate as sole source of nitrogen and 470 mM Chlorate. These plates were incubated at 28 C +/- 1 C for five days.

It was found that mutants arose at a frequency of 10 and 8 in $10^6$ viable conidia of \textit{B. bassiana} and \textit{M. anisopliae} respectively. These mutants were isolated and purified further on a minimal medium containing chlorate and glutamate. The ability of these mutants to grow on nitrate, nitrite, ammonium, hypoxanthin, proline and glutamate as sole source of nitrogen was assessed (Table 2). Of the 18 mutants tested, two each of \textit{B. bassiana} and \textit{M. anisopliae} had phenotypes indicative of \textit{niaD}. Two were found to be \textit{crnA} of \textit{M. anisopliae} while one \textit{crnA} of \textit{B. bassiana} was noticed. It was found on testing two \textit{niaD} mutants (Figure 1) designated \textit{niaD-1} and \textit{niaD-4} of \textit{B. bassiana} and \textit{M. anisopliae} respectively, that reversion to nitrate prototrophy was less than one in $10^7$ viable conidia, whereas reversion frequencies of spontaneous mutants was more than 100 and 60 in 10\textsuperscript{7} viable conidia of \textit{B.bassiana} and \textit{M. anisopliae}, respectively. Hence EMS treated \textit{niaD} mutants should be suitable for future experiments involving protoplast fusion and transformation.
